1 27 **ABSTRACT**

2  
3 28 **BACKGROUND:** The aim of this study was to investigate the effects of basketball  
4  
5 29 match-play on ankle dorsiflexion range of motion (ROM) and countermovement (CMJ)  
6  
7 30 performance, and their association with internal match load.

8  
9 31 **METHODS:** Thirty semi-professional basketball players participated in this study.  
10  
11 32 Ankle dorsiflexion ROM and bilateral CMJ performance were evaluated before (pre-  
12  
13 33 match) and immediately after match-play (post-match). Also, ankle dorsiflexion ROM  
14  
15 34 was measured 48h post-match. Furthermore, in each player, the ankle dorsiflexion ROM  
16  
17 35 scores were categorized as normal or restricted according to the reference values  
18  
19 36 previously reported (>2 cm of change from baseline pre-match to post-match and to 48h  
20  
21 37 post-match).

22  
23 38 **RESULTS:** Ankle dorsiflexion ROM was increased post-match from pre-match in  
24  
25 39 dominant and non-dominant limbs and decreased 48h post-match compared with  
26  
27 40 immediately post-match measures in both limbs. Approximately 20% of all players  
28  
29 41 showed restricted ankle dorsiflexion ROM values 48h post-match. CMJ performance was  
30  
31 42 higher post-match than pre-match.

32  
33 43 **CONCLUSIONS:** Ankle dorsiflexion ROM is still reduced 48h after a competitive  
34  
35 44 basketball match in semi-professional basketball players. The implementation of specific  
36  
37 45 recovery strategies aiming at minimizing a decrease in ankle dorsiflexion after a match  
38  
39 46 might be considered to reduce the likelihood of ankle injury.  
40

## 49 INTRODUCTION

50 Basketball requires players to perform a very-high amount of repeated intermittent  
51 activities such as changes-of-direction, dribbles, shuffles, sprints, accelerations and  
52 decelerations, jumps and landings.<sup>1</sup> Due to these high-intensity movements and actions  
53 required during the course of matches, it would be advisable to quantify the training loads  
54 in order to know whether players are coping with the match demands.<sup>2</sup> In this sense,  
55 Gabbett<sup>3</sup> speculated that both inappropriate and excessive training loads would result in  
56 an increase of injury rates in athletes. In basketball, previous studies have showed an  
57 average injury rate of 7.0 to 19.1 injuries per 1000 hours played.<sup>4, 5</sup>

58  
59 A restricted ankle dorsiflexion range of motion (ROM) is considered a risk factor for  
60 patellar tendon injury<sup>6</sup>, ankle injury<sup>7</sup>, anterior cruciate ligament (ACL) rupture<sup>8</sup>, Achilles  
61 tendinopathy<sup>9</sup> and hamstring strain<sup>10</sup> in several sports. Specifically, the cut-off score of  
62 >2 cm has been previously suggested as the smallest worthwhile change to identify  
63 impairments in ankle dorsiflexion ROM.<sup>11</sup> This could be due to the fact that a meaningful  
64 reduction of ankle dorsiflexion ROM may restrict the ability to pass the leg forwards over  
65 the foot<sup>12</sup> and to lower the centre of mass during squat-type movements.<sup>13</sup> In addition,  
66 lower ankle dorsiflexion ROM might induce an overload of plantarflexor muscle-tendon  
67 units in a more lengthened and everted position during landing.<sup>9</sup> These alterations may  
68 lead to abnormal lower-limb biomechanics during closed chain strengthening exercises<sup>14</sup>  
69 and to increased landing forces and stiffness after a jump, significantly increasing the  
70 injury risk.<sup>15</sup> For example, reduced ankle dorsiflexion during a squat implies an increased  
71 knee valgus and medial knee displacement, decreased quadriceps activation, and  
72 increased soleus activation.<sup>13</sup>

1 73 In this sense, most authors have examined ankle dorsiflexion characteristics before the  
2  
3 74 commencement of the season or in resting situations.<sup>16</sup> However, the ability of this  
4  
5 75 assessment to capture fluctuations in ankle dorsiflexion ROM profile in-season,  
6  
7 76 specifically in response to match-play, has not been studied yet.<sup>16</sup> Previous research has  
8  
9 77 reported that team sports are characterized by intermittent activities in which the high-  
10  
11 78 intensity actions are significantly reduced in the final stages of a competitive match-  
12  
13 79 play<sup>17</sup>, likely associated with match-induced fatigue.<sup>18</sup> In this sense, it has been  
14  
15 80 demonstrated a decrement of lower limbs' power performance after match-play and  
16  
17 81 subsequently this measure can be one of the potential factors in injury causation in sport.<sup>19</sup>  
18  
19 82 Fatigue is known to reduce sports performance through the decrease of muscle strength,  
20  
21 83 neuromuscular control, and ROM.<sup>19</sup> In this regard, recent studies have analyzed the  
22  
23 84 impact of match-play on ankle dorsiflexion ROM in soccer<sup>16</sup> and in Australian football<sup>11</sup>  
24  
25 85 but there is no information regarding this effect in basketball.  
26  
27  
28  
29 86  
30  
31 87 Additional to ankle dorsiflexion ROM, vertical jump performance has been demonstrated  
32  
33 88 as a valid indicator to evaluate match-related fatigue during the course of basketball  
34  
35 89 matches.<sup>20</sup> Specifically, countermovement jump (CMJ) performance has routinely been  
36  
37 90 used in basketball players' performance to monitor neuromuscular readiness.<sup>20</sup> Although  
38  
39 91 basketball is a demanding team sport which can induce fatigue and consequently a decline  
40  
41 92 in players' power performance during the matches, previous studies with young players  
42  
43 93 found that jumping performance was similar before and after matches.<sup>21, 22</sup> However, no  
44  
45 94 research has investigated the effects of basketball match-play on semi-professional senior  
46  
47 95 players' vertical jump performance. This fact can provide relevant information for  
48  
49 96 strength and conditioning staff in order to design population-specific strategies during  
50  
51 97 training sessions.  
52  
53  
54  
55

1 98  
2  
3 99 To implement specific training strategies aimed at maximizing on-field performance, it  
4  
5 100 could be useful to understand the match-related fatigue in terms of ankle dorsiflexion  
6  
7 101 ROM and vertical jump performances after official matches. Therefore, aim of this study  
8  
9 102 was to investigate the effects of basketball match-play on ankle dorsiflexion range of  
10  
11 103 motion (ROM) and countermovement (CMJ) performance, and their association with  
12  
13 104 internal match load.  
14  
15  
16 105

## 18 106 **METHODS**

### 20 107 **Subjects**

22 108 Thirty male semi-professional basketball players (age:  $21.8 \pm 4.7$  years, height:  $193.9 \pm$   
23  
24 109  $8.4$  cm, body mass:  $90.4 \pm 13.7$  kg, training experience:  $14.5 \pm 4.7$  years) volunteered to  
25  
26 110 participate in this investigation. Players belonged to three different teams of the Spanish  
27  
28 111 National Basketball League, and regularly took part in 5 training sessions (a total of 371  
29  
30 112  $\pm 10$  min) per week, besides being involved in an official match on weekends during the  
31  
32 113 2017-2018 competitive season. Participants were classified into three individual playing  
33  
34 114 positions: guards ( $n = 14$ ), small forwards ( $n = 5$ ) and centers ( $n = 11$ ).<sup>23</sup> The inclusion  
35  
36 115 criteria were: to be healthy and actively competing at the time of the study, to not have  
37  
38 116 ankle pain nor have taken any type of medication for the treatment of pain or  
39  
40 117 musculoskeletal injuries at the time of the study and to be involved in regular training  
41  
42 118 during the last month prior to the investigation. Before the start of this investigation, all  
43  
44 119 players were fully informed about the testing and the written informed consent was  
45  
46 120 obtained. This investigation was performed in accordance with the Declaration of  
47  
48 121 Helsinki 2013 and was approved by an institutional Ethics Review Committee (code:  
49  
50 122 DPC.VMP.01.18).  
51  
52  
53  
54  
55

1 123

2  
3 124 **Experimental approach to the problem**

4  
5  
6 125 A cohort design was used to evaluate the acute effects of a basketball match-play on  
7  
8 126 unilateral ankle dorsiflexion ROM and CMJ performance (Figure 1) from February to  
9  
10 127 April in a total of 6 matches. Players underwent a 20 min warm-up consisting of 3-min  
11  
12 128 of low to moderate-intensity running followed by 6–8 min of dynamic stretching that  
13  
14 129 included 2 sets, from low- to high-intensity, with a 15 s rest period between each set (i.e.,  
15  
16 130 straight leg march, forward lunge with opposite arm reach, forward lunge with an elbow  
17  
18 131 instep, lateral lunge, trunk rotations, multi-directional skipping). Before the match (pre-  
19  
20 132 match), within 30 min immediately after the match (post-match) and 48h after the match  
21  
22 133 (48h post-match), the unilateral ankle dorsiflexion was measured by the same investigator  
23  
24 134 and using the same methodology. In addition, CMJ performance was also assessed pre-  
25  
26 135 and post-match. The order of ROM and CMJ tests was randomized across the players but  
27  
28 136 it was maintained constant for each player. The internal load imposed by the match was  
29  
30 137 measured by the session rating of perceived exertion match load (sRPE ML) completed  
31  
32 138 30 min after the end of the competitive game while wellness scores were collected 48h  
33  
34 139 post-match. A week before testing, basketball players were familiarized with all the tests,  
35  
36 140 to reduce the influence of the learning effect. Based on Wollin et al.<sup>16</sup>, player testing order  
37  
38 141 and selection of tested leg were randomly selected prior to the pre-match test. To reduce  
39  
40 142 the interference of uncontrolled variables, all the players were instructed to maintain their  
41  
42 143 habitual lifestyle and training routines and normal dietary intake before and during the  
43  
44 144 study.

55

1 148 **Measurements**

2  
3  
4 149 *Ankle dorsiflexion measures*

5  
6 150 To measure unilateral ankle dorsiflexion for both sides we followed the methods  
7  
8 151 previously described by Calatayud et al.<sup>24</sup> with the Lunge test using the Leg-Motion  
9  
10 152 system test (LegMotion, Check your Motion, Spain) after standardized warm-up  
11  
12 153 performed before pre-match, after match and 48h post-match. Participants were in a  
13  
14 154 standing position on the Leg-Motion system with the tested foot on the measurement scale  
15  
16 155 (Figure 2). The contralateral foot was positioned out of the platform with toes at the edge  
17  
18 156 of it. Each player performed the test with their hands on their hips, with the assigned foot  
19  
20 157 on the middle of the longitudinal line, and just behind the transversal line of the platform.  
21  
22 158 While maintaining this position, subjects were instructed to flex forward the knee to  
23  
24 159 contact it to the metal stick. When the participant could maintain heel and knee contact  
25  
26 160 achieving the maximal distance, the metal stick was progressed away from the knee, and  
27  
28 161 the following achieved distance was recorded. The ankle dorsiflexion testing was  
29  
30 162 performed by one experienced researcher in the clinical area of the basketball court.  
31  
32 163 Dominant leg was defined as the participant's jump leg. Three repetitions were performed  
33  
34 164 in each leg (i.e., dominant and non-dominant), with 10 seconds of passive recovery  
35  
36 165 between trials. The best score among these measurements in each ankle was selected for  
37  
38 166 subsequent analysis. The intraclass correlation coefficient (ICC) of the Leg-Motion  
39  
40 167 system test was 0.96 to 0.98.<sup>24</sup>

41 168

42  
43  
44  
45  
46  
47 169 **### Insert Figure 2 here please ###**

48  
49 170

50  
51 171 *Countermovement Jump (CMJ)*

52

53

54

55

1 172 Bilateral CMJ tests were used to assess the explosive strength of the lower limb muscles.  
2  
3 173 During the jump, hands were held at the hips as described by Núñez et al.<sup>25</sup> From a  
4  
5 174 standing position with straight knees, the player squatted down to ~90° before jumping as  
6  
7 175 high as possible. They were instructed to jump and land in exactly the same place, with  
8  
9 176 the body in an erect position during the jump until landing. Jump tests were performed  
10  
11 177 on a contact mat connected to the Ergo tester (Ergo Jump Bosco System, Italia) unit. The  
12  
13 178 ICC for these tests ranged from 0.94 to 0.96.  
14

15 179

### 16 180 *Internal match load*

17  
18 181 The internal match load was measured by the session sRPE ML. The 10-point scale  
19  
20 182 proposed by Foster et al.<sup>26</sup> was administered 30 min after the end of the basketball  
21  
22 183 matches in order to quantify the self-reported rates of exertion. Players answered the  
23  
24 184 question: how hard was the match? The same person was responsible for asking the  
25  
26 185 question to all players. Then, the RPE score was multiplied by the effective playing time  
27  
28 186 of each player, thus reporting the internal match load (ML) in arbitrary units (AU).<sup>27</sup>  
29  
30 187 Participants became fully accustomed and familiarized to the RPE evaluation during the  
31  
32 188 previous month.  
33  
34  
35  
36

37 189

### 38 190 *Wellness*

39  
40 191 Basketball players completed a well-being questionnaire following the protocol of  
41  
42 192 McLean et al.<sup>28</sup> This questionnaire was filled out 48h after the end of the official match-  
43  
44 193 play. The questionnaire assessed players' fatigue, sleep quality, general muscle soreness,  
45  
46 194 stress levels and mood on a five-point scale. Overall, well-being was then determined by  
47  
48 195 summing up the score of each item. The well-being questionnaire was administered by  
49  
50 196 the same examiner and in an individual and private manner to each player.  
51  
52  
53  
54  
55

197

**198 Statistical analysis**

199 Results are presented as means  $\pm$  standard deviation (SD). We used a magnitude-based  
200 inference approach to identify changes induced by the basketball match-play. The effect  
201 size (ES) with the uncertainty of the estimates shown as 90% confidence intervals (CI)  
202 were used quantify the magnitude of the differences between pre-match, post-match and  
203 48h post-match concerning unilateral ankle dorsiflexion and CMJ performance. The same  
204 procedure was used to compare playing positions (i.e., guards, small forwards and  
205 centers). Furthermore, ankle dorsiflexion ROM scores for each participant were  
206 categorized as normal or restricted according to the reference values previously reported  
207 as clinically meaningful (difference  $>2$  cm).<sup>11</sup> The ES were classified as follows: trivial  
208 ( $<0.2$ ), small (0.2–0.6), moderate (0.6–1.2), large (1.2–2.0), very large (2.0–4.0) and  
209 extremely large ( $>4.0$ ).<sup>29</sup> The percentage chances were then qualified via probabilistic  
210 terms and assigned using the following scale: 25–75%, possibly; 75–95%, likely; 95–  
211 99.5%, very likely;  $>99.5\%$ , most likely.<sup>29</sup> If the chance of having beneficial/better or  
212 detrimental/poorer was  $>75\%$ , the true difference was considered clear (substantial).  
213 Inference was classified as unclear if the 90% CI overlapped the thresholds for the  
214 smallest worthwhile positive and negative effects.<sup>29</sup> The relationships between the  
215 relative change ( $\Delta\% = ((\text{post-match or 48 h post-match} - \text{pre-match} / \text{pre-match}) * 100)$ )  
216 of the players' unilateral ankle dorsiflexion and CMJ performance and the sRPE ML were  
217 examined using Pearson's correlation coefficients, with 90% CL. The following scale of  
218 magnitudes was used to interpret the magnitude of the correlation coefficients:  $<0.1$ ,  
219 *trivial*; 0.1– 0.3, *small*; 0.3–0.5, *moderate*; 0.5–0.7, *large*; 0.7–0.9, *very large*;  $>0.9$ ,  
220 *nearly perfect*.<sup>29</sup>

221

1 222 **RESULTS**

2  
3 223 Basketball players' internal match load and wellness perception are presented in Table 1.

4  
5 224 For all players, the internal load measured by sRPE ML score was  $107.70 \pm 69.14$  AU and

6  
7 225 the wellness value was  $18.33 \pm 1.63$  AU. Unclear differences among playing positions

8  
9 226 (i.e., guard, small forward and center) were found in the sRPE ML. On the other hand,

10  
11 227 while unclear differences in wellness were reported between guards and centers, lower

12  
13 228 wellness values was observed in guards (*likely; small*) and centers (*likely; moderate*) in

14  
15 229 comparison to small forwards.

16  
17 230

18  
19 231 **### Insert Table 1 here please ###**

20  
21 232

22  
23 233 Table 2 shows the pre-match, post-match and 48h post-match values of the ankle

24  
25 234 dorsiflexion ROM. An increase in dominant and non-dominant ankle dorsiflexion ROM

26  
27 235 was found from pre-match to post-match. In contrast, lower values were observed from

28  
29 236 post-match to 48h post-match in all basketball players (*most likely; small* and *most likely;*

30  
31 237 *moderate*), guards (*very likely; moderate* and *most likely; large-moderate*), small

32  
33 238 forwards (*likely-most likely; moderate* and *very likely-most likely; moderate*) and centers

34  
35 239 (*likely; small* and *most likely; small*). However, no substantial changes were observed in

36  
37 240 dominant and non-dominant ankle dorsiflexion ROM from pre-match to 48h post-match.

## 259 **DISCUSSION**

260 The aim of the present study was to investigate the effects of basketball match-play on  
261 ankle dorsiflexion ROM and CMJ performance measures. In addition, we attempted to  
262 quantify the internal basketball match load and the wellness perception 48h after match-  
263 play for each playing position and to analyze the association between sRPE ML and  
264 wellness (48h post-match), and changes in post-match ROM and CMJ. This is the first  
265 study that analyzes the acute effects of basketball match-play on ankle dorsiflexion ROM  
266 measures. The main results showed that basketball match-play acutely produced an  
267 increase on ankle dorsiflexion ROM and CMJ performance in all players. In addition,  
268 ankle dorsiflexion ROM decreased 48h post-match in both limbs compared to the values  
269 obtained just after the end of the game in all players and in some specific positions (i.e.,  
270 guards and small forwards). Specifically, by calculating the number of players with

1 271 greater restrictions than the cut-off score of 2 cm in ankle dorsiflexion ROM measures  
2  
3 272 between pre-match vs 48h post-match, 20% of the players were identified as restricted.  
4  
5 273 The sRPE ML has been considered a useful tool to quantify the internal basketball match  
6  
7 274 load, mainly due to its low cost, user-friendly nature and associated high-speed data  
8  
9 275 processing (13).<sup>26</sup> It has been implemented not only during training sessions<sup>30</sup> but also in  
10  
11 276 official matches.<sup>31</sup> This tool has become a very relevant strategy to assess physical load  
12  
13 277 imposed by basketball competition/training not only in investigation but also in the  
14  
15 278 applied field. The sRPE ML showed in our study were lower than those reported by  
16  
17 279 previous studies with young and senior basketball players.<sup>31-33</sup> While in the current study  
18  
19 280 basketball players reported sRPE ML values of  $108 \pm 69$  AU, other studies showed higher  
20  
21 281 values of sRPE ( $\approx 450$ -500 AU).<sup>34</sup> These differences can be explained because Manzi et  
22  
23 282 al.<sup>34</sup> used the complete duration of the match, including all stops from the start to the end  
24  
25 283 of the game while in our analysis, the perceived exertion of each player was multiplied  
26  
27 284 by the individual minutes played, which better reflects the involvement of the player  
28  
29 285 during the game. In addition, we observed no substantial differences in sRPE ML among  
30  
31 286 playing positions (i.e., guard, small forward and centers). Considering that few studies  
32  
33 287 has analyzed the internal load imposed to basketball players<sup>34,35</sup>, these data could provide  
34  
35 288 insightful information to coaches in order to design training sessions that replicate  
36  
37 289 competition conditions. On the other hand, regarding wellness, higher values were  
38  
39 290 observed in small forwards in comparison to guards and centers. This better recovery state  
40  
41 291 is probably caused by the their playing style as small forwards display less contact with  
42  
43 292 opponents and lower number of acceleration and deceleration compared to the players  
44  
45 293 acting in the other positions.<sup>35</sup> Nevertheless, further research is warranted to investigate  
46  
47 294 the relationship between physical demands imposed on basketball players and post-match  
48  
49  
50  
51  
52  
53  
54  
55

1 295 exertion and wellness, especially because in this study there was only one time point (48h  
2  
3 296 post-match) to quantify the latter.  
4

5 297 Ankle dorsiflexion ROM seems to be important in several sport-specific tasks in order to  
6  
7 298 facilitate ground clearance and preparation for foot impact.<sup>9, 13, 14</sup> However, restricted  
8  
9 299 ankle dorsiflexion ROM could alter movement mechanics in these actions<sup>36</sup> and  
10  
11 300 consequently increase the injury risk of the athletes.<sup>15</sup> For example, Wollin et al.<sup>16</sup> found  
12  
13 301 a reduced dorsiflexion ankle ROM of 6.7% after match-play compared to pre-match in  
14  
15 302 elite football players. However, the results obtained in the present study showed that a  
16  
17 303 basketball match-play induced an increase of ankle dorsiflexion ROM immediately post-  
18  
19 304 match compared to pre-match values in all players, guards, centers and small forwards in  
20  
21 305 both lower limbs. Increases in ankle dorsiflexion ROM immediately post-match are likely  
22  
23 306 due to the increase in tissue extensibility caused by temperature increment which leads to  
24  
25 307 a reduction of the viscous resistance of muscle tissues and joints.<sup>37</sup> These findings suggest  
26  
27 308 that the physiological effect caused by a basketball match-play on the ankle dorsiflexion  
28  
29 309 ROM did not induce higher injury risk. In this regard, although several injuries is  
30  
31 310 attributed to the restriction of ankle dorsiflexion ROM, it can be produced by different  
32  
33 311 structural damages and caused by or related to many other factors, such as a poor  
34  
35 312 conditioning, repetitive loading, and/or abrupt increase in training load.<sup>3</sup>  
36  
37

38 313 In addition, the current results showed decreased ankle dorsiflexion ROM 48h post-match  
39  
40 314 compared with after post-match values in all basketball players (and clinically relevant  
41  
42 315 changes compared to pre-match in 20% of players) and in each playing position in  
43  
44 316 dominant and non-dominant limbs. These findings are partially supported by Wollin et  
45  
46 317 al.<sup>16</sup>, who did not report significant results but a trend towards reduced dorsiflexion ankle  
47  
48 318 ROM 48h post-match (1.9% compared to post-match). Related to these results, Souglis  
49  
50 319 et al.<sup>38</sup> described the inflammatory, muscle damage and metabolic indices response in  
51  
52  
53  
54  
55

1 320 basketball players after playing a match, lasting from 13 to 37h post-game, and  
2  
3 321 researchers concluded that competition provoked muscle damage shown by different  
4  
5 322 blood markers (creatine kinase, and lactate dehydrogenase). Therefore, this ROM  
6  
7 323 reduction may be related to muscle damage generated during the match, which might be  
8  
9 324 attributed to induced impairments in the mechanical and neural properties of the muscle-  
10  
11 325 tendon unit<sup>39</sup>, that could lead to a reduction in players' ankle dorsiflexion flexibility 48h  
12  
13 326 post-match. Based on these results, there is a greater risk of injury at 48h post-match;  
14  
15 327 therefore, preventive stretching exercises focused on soleus, gastrocnemius and  
16  
17 328 hamstring muscles should be implemented during the specific recovery program within  
18  
19 329 48h after match-play, with the aim to avoid future injuries.

20  
21  
22 330 An assessment of power performance pre- and post-match-play on basketball players can  
23  
24 331 be relevant due to continuous high-intensity actions such as jumps,  
25  
26 332 accelerations/decelerations and changes of directions performed during match-play.<sup>1</sup> Our  
27  
28 333 results, in contrast to previous studies which revealed no changes pre- to post-match-play  
29  
30 334 on vertical jump performance<sup>21, 22</sup>, showed an enhancement in CMJ performance  
31  
32 335 immediately post-match in all players, guards and centers. However, no substantial  
33  
34 336 differences in CMJ performance were observed in small forwards. These differences  
35  
36 337 could be explained, because the basketball's specific actions can elicit the post-activation  
37  
38 338 potentiation effect on players.<sup>40</sup> However, given that no associations have been found  
39  
40 339 between sRPE ML and  $\Delta\%$  post-match change in CMJ performance, it would be  
41  
42 340 appropriate to quantify the match load providing other load indicators (especially the  
43  
44 341 external ones) in order to better understand the changes on vertical jump performance.

45  
46 342 Although the present study is believed to be the first to analyze the acute effect of  
47  
48 343 competitive basketball match-play demands on ankle dorsiflexion ROM, some limitations  
49  
50 344 exist as to the interpretation of data. First, the sample was composed of high performance  
51  
52  
53  
54  
55

1 345 and well-trained basketball players but the size can be considered as small. For this  
2  
3 346 reason, the effect size was calculated to determine the magnitude of the effect,  
4  
5 347 independent of the sample size, and confidence intervals were provided to account for  
6  
7 348 inter-individual variability in the variables under investigation. A second limitation of  
8  
9 349 this study was the analysis of only one competitive match, and future studies investigating  
10  
11 350 ankle dorsiflexion ROM responses to match-play after multiple matches or in a multiday  
12  
13 351 competition is needed to fully establish the changes in ROM that occur in the related  
14  
15 352 muscle group after competition. Finally, this study did not investigate the CMJ 48h post-  
16  
17 353 match due the coach did not allow this evaluation; hence, future studies should investigate  
18  
19 354 CMJ 48h post-match.  
20  
21  
22  
23  
24

## 25 356 **CONCLUSIONS**

26  
27 357  
28  
29 358 The present study showed that immediately after basketball match-play the players' ankle  
30  
31 359 dorsiflexion ROM and CMJ increased; however, after 48h post-match the ankle  
32  
33 360 dorsiflexion ROM was reduced in comparison to pre-match (>2 cm in 20% of players)  
34  
35 361 and post-match (group average). These findings suggest that a basketball match-play did  
36  
37 362 not reduce ankle dorsiflexion and thus a higher risk of injury cannot be associated to  
38  
39 363 deteriorated ankle ROM during the game. However, during the 48h following the match,  
40  
41 364 players require specific recovery strategies (i.e., stretching) in ankle joint before returning  
42  
43 365 to strong training or match-play. In addition, our findings showed that basketball match-  
44  
45 366 play induced lower wellness value in guards and centers in comparison to small forwards;  
46  
47 367 however, no differences were found between playing positions with regards to sRPE ML.  
48  
49 368 So, further research could investigate the relationship between these physical demands  
50  
51 369 imposed to basketball players and wellness post-match values.

18 515 **Competing interests.**

19 516 The authors report no conflicts of interests with contents of this paper.  
20 517

21 518 **Authors' contributions.**

22 519 VM conceived the research idea and collected the sample data. DC analyzed the data and  
23 520 statistically interpreted the findings. VM prepared the manuscript and FN, JDC, JR and  
24 521 DC critically revised the article, read and approved the final manuscript.  
25 522

26 523 **Acknowledgements**

27 524 The authors acknowledge all participants for their valuable and essential collaboration  
28 525 in the study.
